1 Introduction

We, the people of the Information Age, are surrounded with technologies providing us information or making our lives easier. We benefit from machine-processed informations and in many areas we are totally dependent on computers controlling the environment around. The IT segment is fast paced and innovative. New technologies emerge every day, but sometimes lifetime is as short as the development time. Nevertheless, there are still many information systems based on various programming languages up and running, containing numerous priceless data. The improvements made in networking and the Internet over the years changed the view we anticipate information systems. Nowadays we see need for connecting them together to benefit from code already created and running to provide input data or business logic. Although not every system has the right interface to be interconnected and is ready or designed to operate in complex environment. All of that creates the base ground from which integration frameworks raise to satisfy already existing demand.

The demand to enable interoperability across platforms, programming languages, data formats and interfaces. Main goal of an integration framework should be to simplify the complexity of integration and also unify the management. Also it can not be hard to adopt to actually bring benefit to users rather than discourage them with difficult learning process.

Apache Camel project is one of the integration frameworks used for above mentioned purpose. It is open source based, developed under Apache with a great help from community. The main advantage of Camel is its modularity, for every new communication protocol just a new component needs to be added. That enables Camel to keep the core lightweight and stable to provide the right tools for every given scenario.

The purpose of this thesis is to create new Camel component. It should act as HTTP provider in Camel. This component should benefit from yet another open source project JBoss Undertow. Undertow is web server, written in Java from scratch and based on non-blocking principles. This component was required through community process as a new feature to incorporate into the distribution. The reasons might

not be clear at first as there are already several other HTTP components available in the Camel distribution. Similarly to Camel Undertow is lightweight and easy to embed. It is also used in Wildfly application server. The chapter 2.6.2 contains performance comparison of various HTTP server implementations. From the result it can be seen that among Java based web servers Undertow is constantly placing in the top three. The Undertow is also gaining popularity inside the open source community. It is still relatively young project that might have bright future. The thesis creates base for the future cooperation of Camel and Undertow projects.

Based on community given approach the new component is named Camel Undertow.

The thesis itself is divided into five thematic parts. The first chapter contains introduction and motivation with the overview of the following chapters.

The second chapter introduces all the technologies used in implementation. The text is not detailed to provide just the most important facts and link to detailed sources for further reading.

Analysis and design are summarized in the third chapter. It contains diagrams and reasons to support design decisions.

The next chapter illustrates implementation of the new component created for this thesis.

The last chapter is conclusion of the work.

2 Technologies

This chapter introduces technologies that are used for implementation of Camel Undertow component. Every sub-chapter consists of description and typical uses cases, where the specific technology excels.

2.1 Apache Camel

Apache Camel is open source rule-based mediation framework implemented in Java. The core of the framework is formed around the theory of EIPs¹ by Gregor Hohpe and Bobby Wolf. It creates base layer in integration efforts across various applications, e.g. in stand alone routing, communication of web services, enterprise messaging solutions or full integration platforms (also known as ESB²) like Apache ServiceMix, JBoss Fuse or Fuse Service Works. Based on previously mentioned fact, Camel is not an enterprise service bus on its own, for instance it does not provide container support or messaging broker. It aims to be lightweight, easy to adopt and extendable for developers. There is also no complex class hierarchy or APIs rather emphasising the focus on integration tasks.

2.1.1 Fundamental principles of Camel

The idea behind Camel is to get the maximum potential from the theory of EIPs and to efficiently minimize the lines of source code needed to implement integration scenarios. Therefore a convention over configuration approach is used to describe the task in declarative way by domain-specific language (DSL). The Camel's DSL creates common way for developers to integrate the applications which is easy to learn and afterwards apply, regardless of transport protocols, delivery format, payload encoding or endpoints connectors. There is no canonical format or assumption of data format directly hardcoded in the framework. This fact gives developers working on integration task no limiting condition, literally any kind of system could be merged together.

-
1. EIP - Enterprise Integration Pattern
 2. ESB - Enterprise Service Bus

Routing and mediation engine

Routing engine enables users to define custom rules for routing messages, acceptance strategy for sources sending to endpoint, also add processors on the way to modify the payload and finally decide to which destination message is delivered.

Domain-specific language

The format of DSL varies by the preference or experience of individual. It is not bound to Java language only, whatever developer likes Java, XML, Groovy, Ruby or even Scala.

Example 2.1: Java DSL definition of route

```
from("undertow://localhost:8888/myapp")
    .to("file:log/access.log");
```

Example 2.2: XML definition of route

```
<route>
  <from uri='undertow://localhost:8888/myapp' />
  <to uri='file:log/access.log' />
</route>
```

Example 2.3: Scala definition of route

```
from "undertow://localhost:8888/" -> "file:log/access.log"
```

Modular implementation

The next key feature, that supports wide adoption of the framework in integration world, is modularity. The Camel can be easily extended to consume or to produce data to endpoint. Out of the box it comes with handful of components to start with, called camel-core including

bean, file, log, mock. Following the structure given by the framework and extending core classes developers are able to provide solution to whatever unique system you could imagine. On top of that, there are many more developed by Apache community and third-parties³. The most common integration scenarios can be served by already existing components to integrate JMS, web services (SOAP or REST), database connections, filesystem resources or mobile push services.

Automatic type converters

Built-in automatic type converter is able to work with more than 150 class types out of the box. For most of the scenarios the converter is available, but also custom ones can be implemented easily. This feature is one of the most favorite in the community. It can be easily triggered by the following example which demonstrates that method used to retrieve body takes as a parameter desired return type, the converter is used without any further interaction from the calling code.

Example 2.4: TypeConverter invocation

```
//direct use of TypeConverter
TypeConverter tc = consumer.getEndpoint()
    .getCamelContext().getTypeConverter();
ByteBuffer bodyAsByteBuffer =
    tc.convertTo(ByteBuffer.class, body);

//automatic trigger under the hood
ByteBuffer bodyAsBuffer =
    message.getBody(ByteBuffer.class);
```

Convention over configuration

The ease of configuration is another fundamental principle to enable developers focus on important task rather than learning number of complicated configuration options. Endpoints can be configured directly in route definitions with URI options as the example demonstrates.

3. [link to components list](#)

Example 2.5: URI options configurations

//pattern to follow

```
"undertow://{host}:{port}/{path}?[{uriOptions}] "
```

```
"undertow://localhost:8080/foo?matchOnUriPrefix=true"
```

Lightweight from the start

From the first line it is designed to be undemanding and resource friendly. Core library of Camel has about 1.6 MB in total with minimum of third party dependencies. Embedding the framework is straightforward regardless of target platform, which can be web application, Spring container, OSGi bundle or various cloud platforms.

2.1.2 Message's types

Various kind of data types are transported in Camel's routes as Messages. There are to main classes that create abstraction of messages, Message⁴ and Exchange⁵.

Message object represents data carried in routes from sender to receiver in system's communication. It consists of body, headers and optional attachments. Every Message has unique identifier (UID). UID format is not strictly given by Camel and dependent on linking protocol. If the protocol doesn't have UID scheme available, there is generic generator provided by framework.

Headers are pairs of key and value, based on very same principle as in HTTP protocol. They contain identifying informations as UID, sender, receiver, type of content, encoding and authentication information.

Body represents payload or content of Message. It has generic Object type to store any kind of content. Acceptance of body type by receiver has to be ensured by application embedding Camel, either by transformation inside the route or by using of automatic type converter.

4. Class of org.apache.camel.Message

5. Class of org.apache.camle.Exchange

Exchange object is a message's container for routing and encapsulates Message. It supports message exchange patterns (MEPs). Property to define messaging style can set in exchange pattern, either one-way or request-response. One-way is called *InOnly* and is used for example in JMS, when sender does not require response. Request-response is defined as *InOut*, most typical example is HTTP transport, when client needs to receive reply. Overview of Exchange's content:

- Exchange ID - unique identifier of Exchange
- MEP - type of messaging style
- Exception - in case of error exception is stored
- Properties - various Camel properties for routing, can be also edited by developers
- In message - input request message
- Out message - output response message, only if the pattern is *InOut*

2.1.3 Architecture overview

The following part will introduce core parts of Camel's design starting from the top. The figure 2.1 illustrates the overview to easier understands the runtime of CamelContext.

Figure 2.1: Overview of CamelContext

Camel context

Camel context is commonly referenced as container, which keeps everything together and provides services during runtime. List of most important services:

- components - used in application, they can be added on the fly
- endpoints
- routes
- type converters
- data formats
- registry - for beans look up. Default is JNDI registry. If Camel is combined with Spring or OSGi container, it uses native registry mechanism for the deployment

Routers and routing

Routes are one of the core concepts used in this framework. The route holds definition of input source and output target. Simple route can be defined as a chain of processors. Every route is absolutely identified by its unique ID, has exactly one input source that is tied to input endpoint and one or many targets.

Routing works under the hood and is not visible to users. It ensures proper routing from the sender to receiver without issues.

Processor

The name is self explaining. Processor is responsible for processing incoming exchange, creation, modification or removal payload and headers. Many processors can be chained together and are invoked by the rules defined in route. Most of built-in processors are implementation of EIPs, as stated previously Camel supports most of integration patterns.⁶ Users has possibility to implement custom processors and add them to route.

6. EIPs in Camel - <http://camel.apache.org/eip.html>

Component

Components add modularity to Camel, they are main extension point. Their task is to be factory of endpoints. The detailed overview of creating new component will be given later in subchapter 2.2.

Endpoint

Endpoints represent sender or receiver on the of message channel. Endpoint is configured by URI, during runtime Camel looks up an endpoint by its URI. Format of URI has three important parts: scheme, context path and options. The scheme contains information about component to be used. In this thesis our scheme is called *undertow*. Context path identifies the location of endpoint, similarly to web page address. Finally the options part is used to deliver specific configuration for component.

One of key task of endpoint is to be factory for creating consumer (receiver) and producer (sender), that can be used in route to get the data flowing.

Consumer

As already stated, consumers can be seen as receivers of messages. It is the starting point of every route, where the message is sent, wrapped with headers and added to exchange. Exchanges created by consumer are afterwards processed in defined chain of processors.

There are two types of consumers, event-driven and polling consumers. They could be also called passive and active consumer. Event-driven consumer is in EIP referred as asynchronous receiver, represents client-server communication strategy. It listens on messaging channel and waits for incoming message.

Polling consumer is active and synchronous, received message has to be processed before polling for another one. Fetches messages from the source. In Camel the scheduled polling consumer can be defined to check for message in time interval.

Producer

Producer is used to create and send a message to an endpoint. It is responsible for creating message and mapping the message content for

the endpoint. In this component it creates HTTP request and acts as HTTP client.

2.2 Component development

Modularity feature is ensured by components as it was already mentioned. They are used to extend Camel and adapt to new integration tasks and add new protocols support without necessity to edit the core implementation of the framework. This part contains the main principles that should be followed to create custom component.

To speed up the development, it is recommended to use Maven archetype as a base for the new component.⁷ The generated skeleton is fully functional HelloWorld example, which is generating dummy messages in intervals. The next step should be naming the component. Component name must be unique among existing components, because it is used in the first part of URI to identify it. List of components distributed with Camel can be found on official web pages.⁸

The hierarchy of classes that need to be implemented is quite simple. There are four main classes that together create Camel component, Component, Endpoint, Producer and Consumer. The names are of course self explaining. The Component class is on top for creating and managing the underlying Endpoint class. Moving to the Endpoint class, it's responsible for creating Producer or Consumer as needed. The custom implementation can extend particular Default-prefixed classes and leverage from the default framework code rather than writing everything from scratch. Extending existing classes ensures following of main principles.

Component class

This class acts as factory of endpoints. Therefore it must implement at least *createEndpoint()* method. The best to achieve it is by extending DefaultComponent. It also contains all parameters that can be set with URI options. Parameters can be annotated with *@UriParams* and then set through reflection by Camel.

7. Maven archetypes - <http://camel.apache.org/camel-maven-archetypes.html>

8. List of components - <http://camel.apache.org/components.html>

Endpoint class

Endpoints are factored by Component class. Its purpose is to manage Producers and Consumers. There should be creation method for both of them. Not every component has to have Producer and Consumer, when it is not needed. If the option is not supported appropriate exception should be thrown to inform user.

Consumer class

Through Consumer the message enters the route. There are several handy classes in default implementation for event-driven and polling consumers. There are no major restriction how to implement this class. In the code UndertowConsumer represents web server that is started by the definition from route and waits for incoming HTTP request to send them down to the route.

Producer class

To be able to send messages outside there has to be Producer class implementation. It is used to establish connection, marshal the data and send them to particular target. UndertowProducer in this thesis acts as HTTP client for sending requests.

2.3 Integration in action

DZone⁹ web site claims to be online community and collection of resources for technology professionals. The web site is well know in community of IT professionals and has outstanding reputation for serving the high quality content. The integration is one of the most prominent topics that DZone focuses on. In 2014 they performed update to its overview research among consumers of integration technologies. It provided overview of usage the integration in practice, recommendations from the top engineers and solution architects and comprehensive comparison of most used solutions. The findings were published in free e-book called *DZone Guide to Enterprise Integration*. This part will summarize the key aspects from the research.[2] The relevance of

9. DZone - <http://www.dzone.com/>

this research is supported by the sample of respondents, most of them have technical background, mainly developers and team leads. The programming language used is Java in 94% of cases.

State of Integration

The integration scenarios are typically covered by integration framework combined with message queues or ESB. In the beginning ESBs were based on Messaging-Oriented Middleware or required Java EE containers for runtime. They gained on popularity with the increased usage of web services, which were quickly integrated. ESB focuses on covering wide range of scenarios, supported with the tools out of box. It ties together multiple endpoints, where central broker does all the heavy lifting of routing, transforming and managing.

On the other hand integration frameworks like Apache Camel or Spring Integration benefit mainly from outstanding support of enterprise integration patterns. They can be paired with message queues and other frameworks to enrich with missing features to be comparable with full ESBs.

Previously mentioned can be viewed as traditional well know and verified approach. On the other hand new emerging trend supported by innovative technological companies seems to be microservices. The idea behind microservices is fundamentally different from ESBs. There is no central point or smart mediator that routes communication, but they rather emphasize smart endpoints and fast transfer channel with minimum of features. Each microservice represents one logical or business feature of the system, it shares common principle with processes in Unix-like operating systems to do single thing right. The communication channels are not tied to process, but they use web services or remote calls.

In conclusion there might be an upcoming shift to more decentralized solutions called microservices. Although most of the scenarios can be still well served with the integration frameworks and ESBs.

Leader Board

The DZone's research provides interesting statistics on usage of technologies. The most popular technology among respondents is Spring

Integration¹⁰ (42%), closely followed by the Camel framework (38%). In the category of ESBs, the winner is Mule ESB¹¹ (16%), then WebSphere ESB¹² (15%) and Oracle ESB¹³ (13%). In conclusion lightweight integration frameworks are more popular taking 63%.

When ESBs and message queues are compared it ends slightly better for the ESBs. The most popular messaging is ActiveMQ¹⁴ (46%) that beats low-latency providers like ZeroMQ¹⁵ or IronMQ¹⁶.

The conclusion based on the above mentioned numbers can be made that developers tends to choose lightweight modular solutions rather than the full stack of unnecessary features.

2.4 Java NIO

Java NIO represents New IO, an alternative implementation to the standard IO API used in the Java language. The key differences include reading data from channels into buffers or vice versa, whenever the standard API uses streams of bytes or chars. The other are non-blocking IO instead of typical blocking IO, when thread is blocked until read or write is completed.

Non-blocking approach means that the execution thread is not blocked, therefore is not waiting for completion of read or write operation instead it redirects it to channel and buffer and continues to operate. Afterwards if the data are available in the buffer even partially, the thread can process it. The write operation acts the same way, data are stored in buffered and written to channel, in the meantime the executing thread can handle some other operation.

The idea is that a single thread can manage multiple input and output operations. The thread is not blocked by reading from one stream, nevertheless do something useful during meantime.

The Channels are similar to Stream approach with some differences. Data are read or written to Buffer. They are also bi-direction in contrast

10. Spring Integration - <http://projects.spring.io/spring-integration/>

11. Mule ESB - <http://www.mulesoft.org/what-mule-esb>

12. WebSphere - <http://www-03.ibm.com/software/products/en/wseshb>

13. Oracle ESB - <http://www.oracle.com/technetwork/middleware/service-bus/>

14. Apache ActiveMQ - <http://activemq.apache.org/>

15. ZeroMQ - <http://zeromq.org>

16. IronMQ - <http://www.iron.io/mq>

to Stream which can be used just for reading or writing. Operations performed on Channels are asynchronously. All those differences come from the usage of Buffer, when data are stored from Channel and not processed directly as in Stream.

The Buffers are used for storing data from Channels as mentioned above. In simple Buffers are wrappers for blocks of memory with methods to access the memory easier.

The Selector is a kind of object monitoring multiple channels for events to further extend capability of single thread. The usage of Selector gives a possibility to use one IO thread to process data from multiple Channels, every time the Channel is ready to be read or written Selector will notify the working thread.

Emphasizing NIO approach developers are able to lower the resource consumption of the application, especially thread pools to handle multiple IO connections and memory usage, because every new thread is associated with some portions of belonging memory. There is ongoing discussion if the multithread or the single thread is better approach. The single thread has benefit of less overhead, meaningful resource allocation and overall lowering the complexity of application, where the thread synchronization and possible deadlocks are not present anymore.

2.5 XNIO

XNIO is community project developed under JBoss, which provides framework abstraction over low level Java NIO and brings simplification over working with Channels, Buffers and Selectors. It extends NIO to support multicast socket and non-socket IO. The project web page claims that XNIO also opens the door to non-obvious optimizations.

One of the most important features of XNIO framework is its unique API, that combines both IO approaches, blocking and non-blocking to bring the best to users. The benefits of low latency of blocking IO with throughput and performance of non-blocking.

Undertow web server is fully based on XNIO framework under the hood, that is one of the reason why developers embedding Undertow can easily switch between blocking and non-blocking processing of incoming requests.

2.6 Undertow

Undertow is a flexible performant web server written in Java, providing both blocking and non-blocking API, which are based on XNIO, the abstraction over Java NIO introduced in previous subchapter.

Undertow has a composition based architecture that allows you to build a web server by combining small single purpose handlers. That gives you the flexibility to choose between a full Java EE servlet 3.1 container, or a low level non-blocking handler, to anything in between.

Undertow is designed to be fully embeddable, with easy to use fluent builder APIs. Undertow's lifecycle is completely controlled by the embedding application.

Overview of key features:

- Lightweight - the core jar is under 1Mb, runtime taking up about 4 MB of heap
- HTTP upgrade support - multiple protocols over HTTP
- Web Socket - full support, including JSR-356
- Servlet 3.1 support
- Embeddable - fully runnable from inside the application
- Flexible - just the right amount of functionality for the task can be used by chaining handler's together

2.6.1 Embedded server

As stated above, Undertow is fully embeddable. There are two ways how to achieve it. The more simple one way is to use builder API and set various properties as handlers, listeners, context paths and listening ports. The second approach is to manually assemble the whole server using XNIO and listener classes directly. Using builder API is sufficient for the purpose of this thesis.

There is no container, that is required to start. Embedded web server is managed by embedding application, also usage and chaining of handlers is under control of the application.

2.6.2 Performance benchmark

The web development company, TechEmpower, regularly updates benchmark results of popular web servers and frameworks. By the results presented on the web pages filtered by language, Undertow is listed as the fastest amongs Java based web servers, in the underlying figure 2.2 is presented the example from results. For the full chart, metrics and enviroment setup follow the link on the company web pages.¹⁷

Figure 2.2: Performance comparison of web servers

17. Web server benchmarks - <http://www.techempower.com/benchmarks/>

2.7 Similar HTTP components

The official Camel distribution already provides several components that have very similar functionality in comparison to Camel Undertow and are considered as HTTP provider components. The following part will summarize the main differences between Camel HTTP, Camel Servlet, Camel Netty, Camel Netty HTTP and Camel Jetty. The last subsection will discuss the motivation for developing Camel Undertow components. Those lines are author's subjective though and summaries.

2.7.1 Camel HTTP

Camel HTTP is one of the core components. It supports only usage of producer, which acts like HTTP client. Therefore it can not be used as input in the route definition. The implementation leverages Apache HttpClient library to produce requests. When there is no special requirement for producing HTTP request, this component should be absolutely sufficient for most basic scenarios.

2.7.2 Camel Servlet

Camel Servlet on the other hand provides support for input message, which is sent to Java servlet published by the endpoint. As the servlet container Tomcat web server is used in the implementation. The full route with consumer and producer endpoints can be achieved by combining Servlet and HTTP components.

2.7.3 Camel Netty and Netty HTTP

This component is implemented on top of Netty framework. The Netty project is also NIO based and should enable quick development of network application. Both blocking and non-blocking sockets are supported. Provides capability for both types of endpoint bind to TCP or UDP protocol. This components should be used if the direct access to above mentioned protocol is needed.

Netty HTTP is extending the parent Netty component and add HTTP transport support.

2.7.4 Camel Jetty

Another HTTP provider component that is based on Jetty server implementation. The Jetty library contains also client support. Therefore both types of endpoint are also supported. Jetty itself is popular as a servlet container and component leverages this fact. The Consumer is implemented in similar fashion and exposes CamelServlet object, which creates input for a route.

2.7.5 Camel Undertow - motivation

It may be confusing why we need another HTTP component, when there are so many already implemented and capable to satisfy user's needs. The easiest answer is, because we can. If there is another web server implementation, why don't create yet another Camel component for it.

Certainly the answer is not so simple. The Camel user's community is wide and divergent. Some of them are satisfied with components coming from distribution. Another group might prefer writing its own component for specific task.

Camel Undertow is based on non-blocking approach to IO operations. It is written from scratch, performance numbers are quite promising also. It is emerging new technology. There is no high demand for Camel Undertow component yet, but in few years the story may be completely different. Undertow might become very popular and dominant among Java web server implementations. Right now it is more a possibility than a necessity.

3 Analysis and Design

This part of the thesis will benefit from all the facts written in previous chapters and provide software analysis for new component. Not every part of software analysis is needed for the purpose of this thesis. Development of components is restricted and follows the skeleton given by the framework. The analysis starts with identifying of requirements which this new component should support. Data flow diagram (DFD) is used to illustrate the context of incoming and outgoing messages and processing inside Camel. Afterwards the design decisions made on the analysis follows.

3.1 Requirements

The main purpose of the thesis defined by the assignment is to integrate JBoss Undertow project with Apache Camel project. The outcome of the integration should be new component that could be used as a web server (HTTP provider). This new component is also required by community in the Apache's Jira.¹

As already mentioned in previous chapter, there is plenty of other components available that can server to the same purpose as Camel Undertow. Why to develop another one? The answer is pretty simple to provide diversity to end users. Undertow is an emerging technology in the community of Java developers. So far it looks very promising as high performance and super lightweight web server. The world of HTTP servers is mainly focused on performance numbers and results of Undertow are in many ways impressive in regard that it is still pure Java implementation. Also it's gaining on popularity due to the fact that it is used in Wildfly application server since version 8.0. In conclusion the fundamental features of Camel and Undertow seem very coherent to tie them together.

The thesis assignment does not provide any detailed listing of requirements. Therefore the following requirements are based upon analysis of similar components acting as HTTP providers and default features for every component:

1. Camel Undertow - <https://issues.apache.org/jira/browse/CAMEL-6577>

3.1.1 Consumer

- ability to create Consumer as HTTP web server
- user defined context path and listening port
- define allowed request methods
- secured access options through HTTPS
- DSL and Spring support

3.1.2 Producer

- send HTTP requests to defined target
- DSL and Spring support

3.2 Data flow diagram

DFD is used to depict the data flow incoming to Consumer and outgoing from Producer.

The figure 3.1 shows Consumer message flow. It is needed to map the incoming HTTP request to Exchange object. Every part of HTTP request should be copied to Exchanges (payload, headers, method type, etc.) to provide users with additional information they could benefit from.

Figure 3.1: DFD illustrates Consumer receiving message

Producer message flow is shown in figure 3.2. The process is reverse to Consumer part. From the Exchange back to HTTP request.

Figure 3.2: DFD illustrates Producer sending message

3.3 Use case diagram

The Use case diagram does not depict the user actors, because Camel Endpoints mainly communicates with applications or APIs.

Figure 3.3: Use case depicts communication through component.

3.4 Design decisions

The design of the component has to follow guidelines given by the Camel framework mentioned in chapter 2.2. Therefore the class hierarchy and structure is already clear.

Undertow will be embedded through builder API and the whole server lifecycle will be controlled by the component. During the research

of client capabilities it was found out that client classes are not suitable for general HTTP client. It was designed to be used in reverse proxy. This fact was confirmed by the lead developer, Stuart Douglas.² In his response, he mentioned that the client is 100% non-blocking and not thread safe. There was discussion in the community about adding a thread safe wrapper, but it is not implemented yet. For the completeness of the component the client classes in the Producer will be used. The implementation will follow points given by Stuart in the email.

Although, users should be warned in the documentation that Producer part is not ideal and should be used with caution. The Producer is exchangeable to other HTTP Producers from components mentioned in chapter 2.6 to ensure proper behavior.

2. Undertow-dev mailing list - <http://lists.jboss.org/pipermail/undertow-dev/2014-December/001072.html>

4 Implementation

The goal of this thesis is to integrate Apache Camel and JBoss Undertow to create new Camel Undertow component. This chapter summarizes the source code and implementation of Camel Undertow component.

The source code for was implemented in Java programming language with regard to restriction of components development mentioned in previous chapters. During the development coding conventions and best practices gained in various courses at Faculty of Informatics were leveraged.

Listing of version used in the source code:

- Java 1.7
- Apache Camel 2.14.0
- Undertow 1.1.1.Final

4.1 Class diagram

Figure 4.1: Class diagram illustrates classes from the source code.

The figure 4.1 depicts class diagram of Camel Undertow component. The exported hierarchy is stripped to only show class names. In the following sections the classes will be discussed in details.

4.2 UndertowComponent class

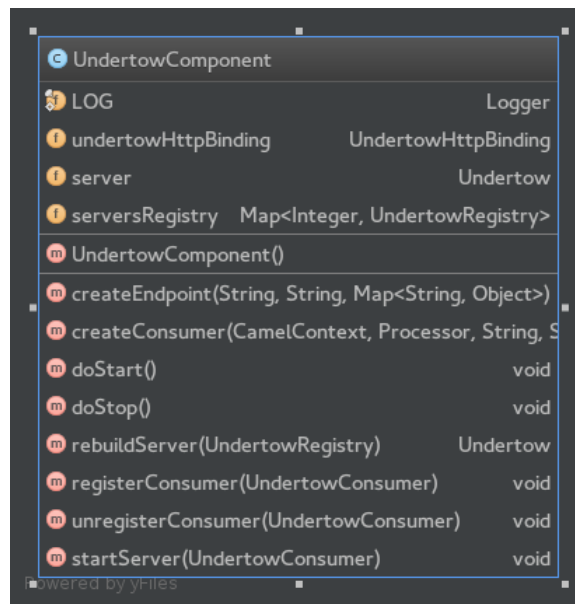

Figure 4.2: UndertowComponent class in more detailed vies.

This class is a starting point of the implemented component. It extends *HttpComponent* to build on the core of Camel code. Its purpose is to be factory of endpoints. Therefore *createEndpoint()* is the most important one.

This method is straightforward. First it reads all the configuration URI parameters and removes them to prevent mismatching them as query parameters. After the incoming URI is cleaned, the Endpoint URI is parsed from the rest.

There is also support for *RestConsumerFactory* to extend configuration of routes and options in REST-style DSL.¹ For this purpose only

1. Camel REST DSL - <http://camel.apache.org/rest-dsl.html>

one new method has to be added, *createConsumer()* In this method the REST configuration is parsed and belonging endpoint is created.

The class also holds configuration of running web server. This fact enables usage of multiple Endpoints with different paths on the same port, but sharing same base configuration. By the base configuration is meant host, port and SSL support. If those three conditions are not satisfied and therefore route is considered misconfigured another route on the same port can not be started.

4.2.1 UndertowRegistry

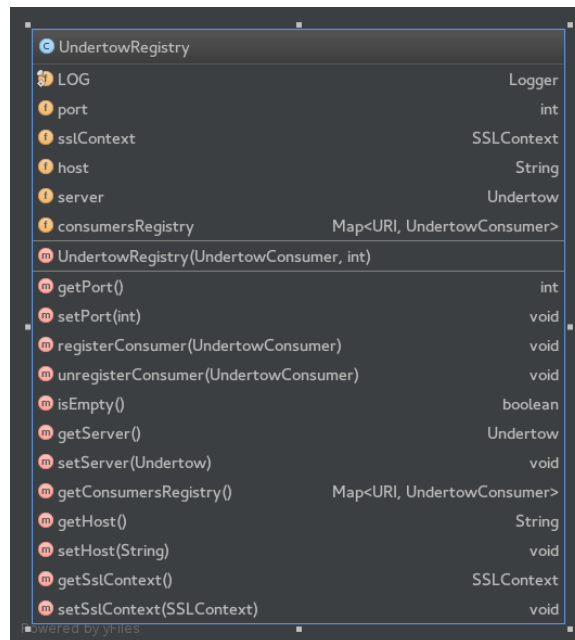

Figure 4.3: UndertowRegistry class in more detailed vies.

The registry of running web servers and belonging Consumers. This utility class is only used inside of *UndertowComponent* class. Through the registry Component is able to access server instance, register and unregister new Consumers. It provides handful of methods to provide convenient access.

This class was added due to the fact that workflow of Builder API is not suitable for runtime modifications. Once the server is built, the

Builder instance can not be retrieved anymore from server instance. Although dynamic modification of server configuration was needed, either by storing object of *Undertow.Builder* or by adding configuration object from which the Builder can be created. That is the reason to implement *UndertowRegistry* class. As mentioned previously the ability to modify server runtime brings benefit of sharing port across Endpoints.

4.3 UndertowEndpoint class

The Endpoint represents a factory for creating Consumers and Producers. This class holds configuration parameters parsed in *UndertowComponent.createEndpoint()*. Primitive types parameters are annotated with *@UriParam* to allow setting through Java Reflection API.

The methods *createProducer* and *createConsumer* are self explaining. Another important one is *createExchange()* which takes *HttpExchange* from web server as input and converts it to Camel Exchange. The main part of this logic is done in *toCamel()* from class *DefaultUndertowHttpBinding*. The binding class provides support for converting incoming HTTP messages to Camel messages and vice versa.

4.3.1 Parameters

Most of the configuration parameters are self explaining. Although in the underlying listing the basic description is given to avoid any confusion.

List of parameters:

- *httpUri* - holds the full URI as defined in route
- *undertowHttpBinding* - the instance of actual binding tied to the Endpoint
- *httpMethodRestrict* - list of comma separated HTTP methods that can be used to access Consumer
- *matchOnUriPrefix* - boolean value which determines if exact or prefix matching of path should be used
- *headerFilterStrategy* - the instance of *HeaderFilterStrategy*, by default the strategy from HTTP component is used

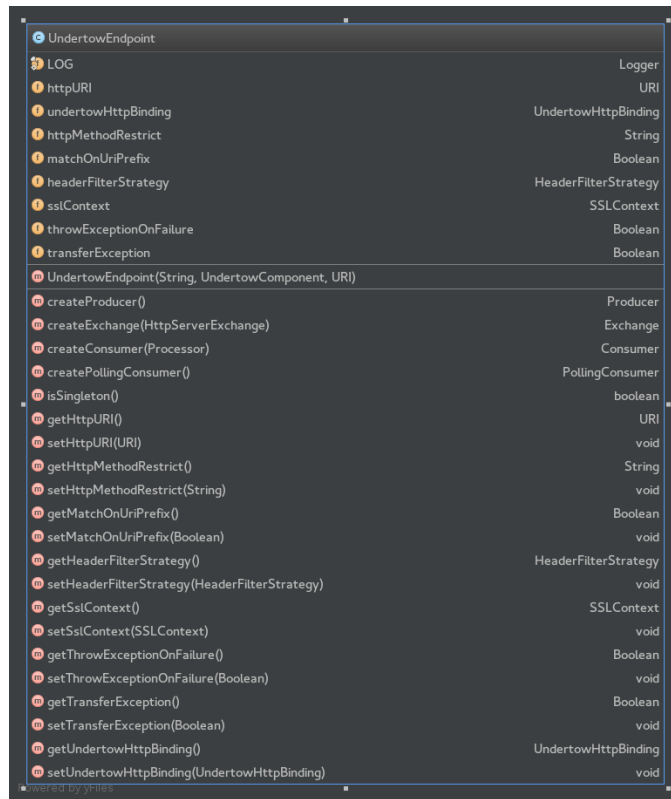

Figure 4.4: UndertowEndpoint class in more detailed view.

- sslContext - provides configuration for the web server
- throwExceptionOnFailure - boolean value whether the exception should be thrown
- transferException - boolean value if the exception should be send back in response

4.4 UndertowConsumer class

One of the essential classes for the component functionality. This class itself starts the Undertow web server and allows it to be used as entry to the Camel route.

There are two possible approaches how to handle incoming request. Java servlet, in particular *CamelServlet* or its extension, can be exposed

to process the incoming messages and send them to route. First prototype was implemented in that fashion. Although it was discarded later due to the fact that Undertow doesn't provide straight way to access servlet instance once deployed to the server. The instance is need during processing to retrieve the request and create particular Exchange. This approach didn't provided the desired amount of control over the processing of incoming request.

On the other hand Undertow is easily extensible with custom handlers. Therefore all the logic of processing the HTTP request is moved to *HttpCamelHandler*, but it still might be considered as a part of Consumer.

The web server is started through methods in *UndertowComponent* class as already mentioned in section 4.2. When new Consumer needs to be added *UndertowComponent.registerConsumer()* is invoked and afterwards *UndertowComponent.rebuildServer()* to reflect change in configuration. Configuration of running server is rebuild and server instance restarted. Upon *doStop()* invocation the Consumer is unregistered from *UndertowRegistry*, the unregister method also checks if there are any other Consumers left to shutdown whole server and release allocated port.

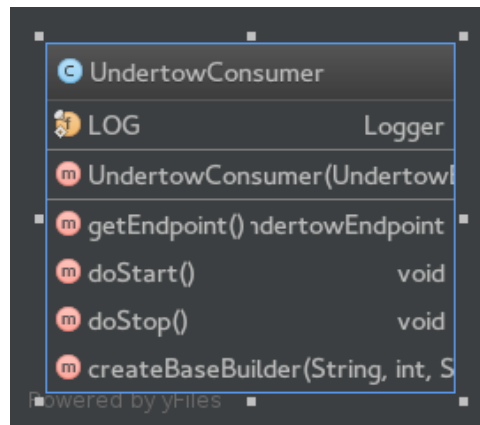

Figure 4.5: UndertowEndpoint class in more detailed view.

4.4.1 `HttpCamelHandler` class

Implementing of custom handlers for Undertow is straightforward. The custom handler needs to implement *HttpHandler* interface which contains only one method *handleRequest()*. Through this method the handler gets to *HttpExchange* object which contains request and response channels, headers and request method type.

The processing of request has few partial conditions to meet to finally proceed to Camel Exchange. If the *OPTIONS* method is received, the handler returns allowed methods. It check for restricted methods from configuration and reject all requests that do not follow the given restriction. If the request method can contain payload (POST, PUT), the request channel is opened to retrieve the body of message, otherwise payload is ignored for other methods.

The Exchange is created through *createExchange* method in Endpoint implementation. The whole *HttpExchange* is used as input. During the Exchange creation *toCamelMessage()* is invoked from the default HTTP binding to copy and filter required headers. The default HTTP binding is provided by class *DefaultUndertowHttpBinding* which implement *UndertowHttpBinding* interface. Conversion of HTTP request to Message benefits from automatic type converter feature. The body is extracted as array of bytes and directly set to Message object, the type converter works under the hood without direct invocation in the binding method. The binding can be changed to custom implementation specified in URI option to modify the behavior, copied headers, etc. When the Exchange is created the Processor can kick off and process it.

Finally after processing of Exchange, the response can be retrieved and send back to requesting client. The standard return code is 200 and body from Camel Message is included, if there is any. In case of error, the return code is 500 and the exception is transferred, if the option parameter is not set to false. The response is created by method *toHttpResponse()* that copies headers and return body as *Object*. The body is afterwards converted to *ByteBuffer* and sent to requesting client.

4.5 `UndertowProducer` class

The implementation of Producer can be considered experimental and is not recommended for usage. The Undertow client classes are not

designed to be used as general HTTP client. As mentioned in previous chapter, they are not thread safe and provides bridge in reverse proxy.

For end users it is recommended to use Camel HTTP or Camel Netty HTTP component as Producer provider.

The actual source code benefits from the recommendations given by Stuart Douglas. It is capable of creating HTTP request from the Message and sending it to target, afterwards receive and read the response. The conversion from HTTP to Camel Message is provided by another handy methods from binding class *DefaultUndertowHttpBinding*.

4.6 UndertowHttpBinding

The binding interface and its implementation *DefaultUndertowHttpBinding* represent the key aspect of how the Messages are created from HTTP requests and vice versa. It is used in Producer and Consumer classes.

It is capable of processing HTTP request in a manner that all headers are extracted and stored in Camel Message, filtered by the given strategy. It is also responsible for reading payload if the requesting method is allowed to have one. Finally the incoming Message is returned to be used in the route.

After processing of the Message is done the binding also maps the response back to HTTP response through the similar process as described above.

The reverse steps are done for the creation of HTTP request in Producer's code. The Camel message is transformed to request and send, when the HTTP response is received, it is stored back to Camel Message.

4.7 Miscellaneous classes

There are two additional classes that provides support methods.

ExchangeHeaders is a copy of *Exchange* class fields that contains header names. Instead of returning them as *String*, this class returns *HttpString* for Undertow to minimize conversion of header names on various places.

UndertowUtil contains just method for simple appending headers to

map.

4.8 Unit tests

The unit tests leverage *CamelTestSupport* classes that provides lot of useful method and mock Endpoints to properly test components. The structure of unit tests follow convention used in Camel project. Every test class represents scenario and has descriptive self-explaining name to be clear for the outside user.

4.9 Examples of usage

5 Conclusion

The primary goal of this master's thesis was to integrate JBoss Undertow HTTP server and Apache Camel project. Under integration is meant design and development of a new Camel component. This new component should be used as a web server (HTTP provider) in the integration framework. As part of this thesis unit test and example of usage in DSL and Spring API should be delivered. Furthermore author should cooperate with community, study Camel component development process and investigate the Undertow implementation.

The outcome of this master's thesis is Camel Undertow component. The new component can be used as HTTP provider to act as Consumer in the route.

As an attachment the source code of the component is included. This component was request by the community, it will be submitted to Apache Camel project as pull request for the review. The latest source code is hosted on GitHub¹. The computer software in general is never absolutely perfect. Therefore there is a possibility that issue and bugs will be found in future during usage or code reviews. All the found issues can be reported through GitHub tools or even be fixed by pull request from the community. The previous also applies for enhancement requests.

The implementation part of this thesis includes the whole source code of the new component. The skeleton was generated by Maven archetype. The main part of work is represented by embedding the Undertow to the Camel. The mechanism for the managing lifecycle and storing configuration of the web server was created. The server is started by Camel itself. Furthermore the binding between HTTP messages and messages transferred inside the Camel routes was needed. The component provides both Endpoint types, Consumer and Producer with the limitation illustrated in following paragraph. The detailed description of implemented classes can be found in chapter 4.

During the research work it was found out that Undertow client libraries are not suitable for implementing a general purpose HTTP client. There was already a discussion in the community about this topic as mention in chapter 3. It should be merged to this component

1. GitHub repo - <https://github.com/dsimansk/camel-undertow>

to harden the Producer implementation. The following fact implies that Producer implementation is not stable and should not be used outside of tech preview scope. It can be replaced by any other provider mentioned in this thesis. Although for the completeness purpose the Producer code is included. The actual implementation will probably vary in future based on the code changes inside Undertow.

For the future development, the main goal is to harden the Producer part once the Undertow client is done by the community. Other requirements submitted from users and community will be added after consideration. Bug fixes should be done as soon as possible, it is highly dependent on current situation and capacity.

In summary to communities involvement in the development process. New component implementation is well documented in various sources online and offline. The Camel community has vital and extensive community that provides many examples, answers on StackOverflow and comprehensive documentation. As mentioned in chapter 2 there are also other very similar component to look for. The Undertow community is definitely much smaller. There is not so many materials available as for Camel definitely. Although almost all questions are answered by the authors of code themselves. The Undertow project is still finding its place under the Sun, the number of users and adopters raises. In a few year it might be dominant web server among Java based implementations. With the increasing interest will also the number of resources available grow significantly.
